

## Editorial

# Impact of COVID-19 shielding on physical activity and quality of life in patients with COPD

COVID-19 is a highly infectious disease that can cause severe respiratory illness, particularly in patients with pre-existing lung conditions such as COPD [1]. To prevent infection during the peak of the pandemic, patients considered to be clinically extremely vulnerable were instructed to “shield” at home, resulting in significant restrictions to usual daily activities and social interaction. In the absence of a preventative vaccine, these public health measures are imperative to reduce transmission of the virus. However, despite this positive aspect, there are likely to be harmful repercussions on people’s physical and mental health.

The adverse effects of physical inactivity in COPD patients are well known and include worsening of health-related quality of life (HRQoL) [2], along with an increased risk of hospitalisations and mortality [3]. The COVID-19 restrictions have posed challenges for the entire population to stay active, with many turning to online resources for support and guidance. However, some patients with limited access or knowledge of how to use these resources may be disadvantaged and might not benefit. In addition to the instruction to shield, the provision of many respiratory clinical services including pulmonary rehabilitation (PR) were suspended and staff redeployed. These programmes remain imperative for those with chronic lung disease, and the demand is now accompanied by an emerging call for rehabilitation/recovery programmes for COVID-19 patients [4]. A wealth of evidence highlights the use of PR for improving exercise capacity, HRQoL

and symptoms. PR also promotes adherence to health enhancing behaviours, facilitating the translation of enhanced exercise capacity to greater participation in physical activities [5]. However, upon completion, these benefits tend to diminish over the first 6–12 months if no on-going exercise is performed [6]. The COVID-19 shielding period could, therefore, have potentially exacerbated the loss of health benefits attained by patients recently completing a PR programme. Studies employing maintenance interventions in the form of supervised and technology assisted exercise have shown some promise in maintaining PR benefits [7].

We followed up a cohort of 10 COPD patients (mean $\pm$ SD forced expiratory volume in 1 s (FEV<sub>1</sub>): 55 $\pm$ 23% predicted), who completed an 8-week PR course between January and March 2020 in the North East of England. Physical activity was measured using accelerometry (Actigraph wGT3X; Actigraph, Pensacola, FL, USA) and the Clinical Visit of Proactive Physical Activity in COPD (C-PPAC) instrument [8] in the week preceding PR, the week following completion of PR and for a week 3 months following completion of PR during the shielding period (April to July 2020). In addition, assessment of HRQoL (COPD Assessment Test (CAT) and Clinical COPD Questionnaire (CCQ)) and psychological wellbeing (Hospital Anxiety and Depression Scale (HADS)) was undertaken. Patients were first contacted by telephone, then an accelerometer and the questionnaires were sent to them in the post. These patients had

been previously enrolled in a study (ClinicalTrials.gov identifier: NCT03749655) investigating the inclusion of physical activity promotion alongside PR and were therefore familiar with the assessment procedures and willing to be monitored.

The results showed a significant and clinically meaningful ( $>600$ – $1100$  steps per day [9]) decrease in daily steps from post-PR to shielding, as well as pre-PR to shielding (figure 1a). The deterioration in daily steps was also accompanied by a significant and clinically meaningful (4 points [8]) worsening in the C-PPAC score from post-PR to shielding (figure 1b), demonstrating not only a reduction in the amount of activity undertaken, but also an increase in the perceived difficulty of conducting physical activity.

A previous multicentre trial involving 157 COPD patients, showed a downward trajectory of physical activity over time, evidenced through a 16% and 18% decrease in daily steps over 6 months and a year, respectively [10]. It is clear from our preliminary data, that “shielding” has further exacerbated physical activity decline, shown through a 39% reduction in daily steps from post-PR to shielding (3 months). The deterioration ( $-1620 \pm 1573$  steps per day) also exceeds that previously exhibited over the year following PR of 600–1000 steps [11, 12]. Furthermore, there was a 32% decline from pre-PR to shielding. This worsening below pre-rehabilitation suggests that not only could some of the benefits attained during PR be lost, but also further deconditioning is likely to have occurred, potentially resulting in worsened long-term disease-related outcomes and an increased risk of comorbidities. Additionally, the decline is significantly higher than that seen in the general UK population ( $-7.8\%$ ) during the lockdown period [13]. This is partly due to the total home confinement of shielding compared with partial confinement for non-vulnerable individuals, as other countries with more stringent restrictions had a greater decline. However, shielding has probably exacerbated the vicious cycle of declining physical activity, leading to increased symptoms and further activity avoidance, which is already evident in COPD patients.

Physical inactivity and deconditioning can often lead to worsening symptoms (breathlessness and leg discomfort), and subsequent worsening of

physical functioning and HRQoL [14]. The data collected from this cohort showed a decline in CCQ scores from post-PR to shielding which exceeded clinically meaningful margins ( $\pm 0.4$  points) for both functional ( $+0.5$  points) and mental domains ( $+0.7$  points) (figure 2). This indicates that shielding caused patients to feel increasingly limited when conducting daily physical activities, which is accompanied with heightened feelings of depression and concerns about breathing. In the general population, the strong link between social isolation and anxiety, depression and cognitive decline is well established [15]. It is perhaps surprising that no statistically or clinically meaningful changes in anxiety or depression (HADS) and health-related quality of life (CAT scores) were seen in this follow-up. It is possible that patients initially felt safer whilst shielding; however, it will be interesting to follow these patients longitudinally to observe if any changes ensue as the uncertainty of the COVID-19 pandemic continues.

## Clinical implications

The findings from this follow-up confirm that the shielding period has caused a significant deterioration in patients’ physical activity within a short time period of 3 months. It is important to consider that this data reflects patients who have recently undergone PR; therefore, it is likely that the effects of shielding are worse for the remaining COPD population who have not recently participated in PR. Due to the well-established association between physical inactivity and adverse clinical outcomes, focus on supporting patients to self-manage their condition and remain physically active at home is imperative. This could be done by using tools, such as tablet computers, pedometers, pulse oximeters and exercise diaries, while providing remote specialist support (*e.g.* over the telephone) to increase patient confidence to exercise at home independently [16].

The pandemic has increased the urgency of developing novel ways of delivering PR programmes and supporting patients remotely. Clinicians continue to explore alternative modes of remote PR delivery and maintenance, including home-based

minimally supervised rehabilitation, internet-based programmes, pedometer-based programmes, yoga and t'ai chi exercise. Indeed, virtual consultations have emerged as a consequence of the pandemic, replacing face-to-face consultations. These have been found to be largely acceptable by both patients and clinicians [17]. In the majority of cases, virtual consultations are taking place over the telephone but there is also the possibility for video consultations, when the patient has access to the internet and can use a tablet computer or smart phone. Video consultations may be conducted over communication platforms (e.g. Microsoft Teams or Zoom) or preferably other secure platforms hosted by the National Health Authorities (such as "Attend Anywhere" in the UK).

Virtual consultations should aim to provide patients with a tailored programme at home including: 1) an educational component on managing the disease; 2) psychological support; 3) nutritional support; 4) advice to be physically

active indoors and outdoors (if in accordance with public health guidance); 5) access to resource packs for improving well-being; and 6) home diaries for patients to record their progress and symptoms that can be reviewed regularly by healthcare professionals. Where resources are limited, patients may be directed to established sources such as the British Lung Foundation or Lung Foundation Australia with access to specifically designed exercise videos, or handbooks for those without internet access [18, 19]. Safety guidance for remotely supervised interventions provided by national respiratory societies [20] should be followed closely to ensure patient safety and correct prescription of exercise. The preliminary data from this follow-up indicates that the instruction to shield in vulnerable, clinical populations might have been a double-edged sword, and clinicians should be wary of long-term detrimental effects when returning to patient treatment.
