

1 Walking alone or walking together: A spatial evaluation of children’s travel behavior to school

2  
3  
4

5 **Abstract:**

6  
7

8 The purpose of this research is to extend our understanding of children’s walking behavior to  
9 school in an understudied region of the world, Istanbul, Turkey. Children (aged 11-17) and their  
10 parents were surveyed to comprehend subjective and objective factors on walking behavior to  
11 school when alone or with someone. Using participatory mapping and GIS, a route detour index  
12 was first created to highlight differences in walking behaviors. A robust spatial analysis,  
13 consisting of spatial statistics and a hierarchical spatial error model, then signified important  
14 survey responses, urban design factors from space syntax, and neighborhood composition and  
15 contextual variables on between-group route choices. Empirical and geovisual analysis  
16 confirmed that accompanied children deviated more from GIS shortest routes to school than their  
17 unaccompanied peers and “hot-spot” analysis showed it was dependent on where children reside.  
18 The spatial error models exhibited notable relations among route choice, children’s age, health,  
19 and gender. Parent attitudes concerning greenspace positively affected children’s longer route  
20 choices, while street connectivity had the **opposite** influence. Surprisingly, neighborhood  
21 walkability did not impact children’s route choice decisions for either group. The results provide  
22 new insights on how to encourage additional walking trips to school.

23 Keywords: Children’s active school travel, walking, GIS, route detour, space syntax, spatial  
24 regression, public health

28 **Introduction**

29  
30

29 Promoting physical activity (PA) in children remains of vital importance for elevating  
30 public health and preventing disease (WHO, 2019) However, 80% of 11-17 year-olds worldwide

31 fail to meet minimum recommended levels of PA (Sallis et al., 2016). When children incorporate  
32 PA into their life, physiological health, cardiovascular fitness, and cognitive ability increase  
33 (Poitras et al., 2016). Since walking is a common form of PA among children, and is a common  
34 commuting mode to school, a key opportunity exists for understanding the means to elevate  
35 active school travel (AST).

36         The literature has shown that several real and perceived factors affect children's AST.  
37 The travel distance to school, population density, land-use diversity, route aesthetics, safety,  
38 sidewalks, and street connectivity – among many others – influence children's AST (Ding et al.,  
39 2011; Panter et al., 2010; Schlossberg et al., 2006; Sun et al., 2018). The relationships remain  
40 incongruent for many of these factors, unfortunately. Land-use diversity was shown to promote  
41 active travel among children in some research (Das and Banerjee, 2021), while others established  
42 weak associations (Yarlagadda and Srinivasan, 2008). Street network design impacts children's  
43 AST and children's route choices while walking to school (Han et al., 2021), but **its** impact has  
44 been inconsistent. Prior research has suggested that space syntax formed urban design metrics  
45 may be more effective **than standard measures of connectivity** at validating this relationship  
46 (Ortegon-Sanchez et al., 2021; Zhao et al., 2022). Ozbil et al., (2021) discovered that important  
47 space syntax metrics corresponded to children's AST. **Hence, space syntax methodology offers a**  
48 **valuable resource with which to provide planners, transport and highway engineers and other**  
49 **policy makers with transformative, evidence-based spatial models, analyses and maps to identify**  
50 **streets to focus investment for traffic reduction measures (e.g., preventing 'pavement parking',**  
51 **installation of new pavements and walkways, densifying street network by installing footways on**  
52 **streets which lack them, etc.) as well as testing alternative intervention scenarios (e.g.,**  
53 **pedestrianisation of specific streets) to encourage a shift to more active modes of travel,**

54 including more “excess” walking to school, which in turn would help support initiatives such as  
55 “low-traffic neighbourhoods” and “15-minute cities.” An additionally important consideration  
56 for understanding a child’s AST are parent effects. Parents are largely responsible for managing  
57 a child’s “mobility license” (Page et al., 2010). Their time, travel patterns, attitudes (i.e., crime,  
58 traffic, personal, or stranger danger), SES, family composition, and physical activity levels are  
59 considerable influences (Mah et al., 2017; Pfladderer et al., 2021; Evers et al., 2014). Route-  
60 specific factors for school-based trips are another feature of children’s AST.

61         Currently, we have a limited understanding of the children’s route choice criteria while  
62 walking to school, especially in less-developed countries such as Turkey (Dias, 2022; Ozbil et  
63 al., 2021). Understanding how to encourage a child’s independent mobility and decision to take  
64 longer walking routes is critical as it positively impacts their physical, social, and personal  
65 development (Schoeppe et al., 2013). The utility of a travel route is largely based on the level of  
66 directness, personal preference, safety/perceptions, mode-choice, and the built environment  
67 (Broach and Bigazzi, 2017; Moran et al., 2018; De Vos et al., 2016). The evidence so far  
68 regarding children remains indeterminate. As an example, Ikeda et al., (2018) found that children  
69 choose routes to school with heavy traffic in Auckland, New Zealand, while Dessing et al.,  
70 (2016) witnessed an opposite relationship in the Netherlands. Companionship levels (i.e.,  
71 walking with parents or friends) may also be an important route choice consideration  
72 (Yarlagadda and Srinivasan, 2008). Lee et al., (2021) posited that when children travelled with a  
73 companion, their decision to choose the most direct path decreased by 39%. Similarly, past  
74 findings indicate that walking with friends might allow children to take longer school journeys,  
75 providing possibilities for environmental engagement (Ross, 2007). The decision to walk alone  
76 or with someone is impacted by a child’s age, gender, parent attitudes, environment, distance

77 from school, and safety issues (Jones et al., 2000; Marzi et al., 2018). Research has indicated that  
78 boys tend to travel alone more than girls (Page et al., 2010); however, Medeiros (2021) found  
79 girls travelled alone as age increased. Parental attitudes also affect a child’s route choice  
80 behavior and independent mobility. Parents are usually worried about “stranger-danger” as well  
81 as the traffic volume around their child’s school (Mammen et al., 2012). Where children live  
82 matters too. For example, a child’s walking route will differ depending on if they reside in an  
83 urban versus a rural environment (Moran et al., 2018). Unfortunately, accounting for these  
84 spatial differences has not been controlled for in the literature.

85         In addressing these research gaps, our study set out to spatially and empirically  
86 investigate children’s walking behaviors to school in an understudied region of the world,  
87 Turkey. Our research has two research objectives: to i) statistically and spatially gain a better  
88 understanding of children’s walking (school) route choices in a Turkish context; ii) apply a  
89 comprehensive spatial analysis – integrating key children attributes and attitudes, parent  
90 characteristics and perceptions, and neighborhood features – to determine their effect on  
91 children’s walking route choices to school when unaccompanied or accompanied.

## 92 **Methods and Data**

### 93 *Study area*

94  
95         The study area in this research was Istanbul, Turkey. It has an area of 5461 km<sup>2</sup> spreading  
96 across two continents and an estimated population of 15,462,452 (TUIK, 2019). The city is the  
97 largest and most important in terms of its role in the economic and cultural transformation of the  
98 country. One out of every three people in Istanbul resides in low socio-economic neighbourhoods  
99 (Demirel, 2017). Bicycling among youth is low in the city (Ozbil et al., 2021); however the 2012  
100 Istanbul household survey indicated that 68.8% of school trips among children consisted of  
101 walking (ITMPPM, 2012). The focus is on the centralized Anatolian section of the city where

102 population density is high and there is a great diversity of demographics, socioeconomic-status,  
103 and land-use. The map (figure S1) in the supplementary document shows the study area,  
104 neighbourhoods, and research participants' residences.

#### 105 *Sampling protocol and survey instrument*

106 A cross-sectional survey instrument was created in 2014-2015 to aggregate children and  
107 parent demographics and attitudes regarding AST in their neighbourhoods. We randomly recruited  
108 11-17 year-old-children (i.e., 6th, 7th, and 8th graders) from twenty schools in selected  
109 neighbourhoods. We chose this age group as middle-school children begin to travel independently  
110 and explore their environment (Hillman et al., 1990). The initial number of participating children  
111 and parents who fully completed the surveys in-person was  $n = 492$  (27% response rate) and  $n =$   
112  $421$  (24% response rate), respectively. For additional details on the human ethics approvals,  
113 sampling approach, and survey development, please see Ozbil et al., (2021).

#### 114 *Children attitudes and character*

115 The attitudes and children characteristics were categorized into three sections: individual  
116 characteristics; commuting habits to school; and perceptions of their neighbourhood (i.e., safety  
117 and the travel environment). Children reported their gender, age, and home address, while their  
118 height and weight were measured using an electronic scale with a stadiometer. The latter  
119 calculation was used to categorise “obese” children using standard thresholds of body mass index  
120 (BMI) using  $((\text{kilograms}/(\text{meters}^2)) \times 703)$  (WHO, 2007; CDC, 2022). Information about their  
121 walking experience to/from school was aggregated using several multiple-choice questions  
122 adapted from prior research (Hume et al., 2006). We also collected their travel mode to and from  
123 school, and accompaniment status (i.e., unaccompanied or walked with somebody) to school. We

124 focused on the trip to school and in doing so built off recent research (Bucko et al., 2021) and all  
125 answers were dichotomized in this research.

### 126 *Household conditions, parent attitudes and attributes*

127 Several parental and household attributes, including mean monthly household income,  
128 education level, and car ownership were aggregated from the survey instrument. The respondents  
129 also reported their level of agreement with twenty-six, five-item, Likert choice sets (strongly  
130 disagree to strongly agree) concerning the safety of their neighbourhood that were based on NEWS  
131 (Neighborhood Environment Walkability Scale) (Cerin et al., 2006). To fully understand latent  
132 factors underlying their attitudes, we employed principal component analysis (PCA) and a Promax  
133 rotation using statistical software (IBM SPSS, version 26). We verified that independent sampling,  
134 normality, and moderate linear relationships between variables (i.e., Spearman's rho  $p < 0.05$ )  
135 were present. A seven-factor solution was found, and each component exhibited eigenvalues  
136 greater than 1.0. Table S1 located in the supplementary materials shows the factor loadings, factor  
137 labels, and **communalities** and table S2 shows measures of central tendency for the sample  
138 population.

### 139 *Neighbourhood variables*

140  
141 Several neighborhood scale contextual and compositional factors were applied in this  
142 research. The compositional variables included population density and socio-economic status  
143 (SES) obtained from the Turkish Statistical Institute (TURKSTAT) and Mahallem Istanbul  
144 (<http://mahallemistanbul.com/>), respectively. The SES of each neighbourhood ranged from zero to  
145 one-hundred: elevated values indicated high SES. The contextual variables consisted of land-use  
146 diversity, greenspace, urban density, walkability, topography, and urban design. The floor area  
147 ratios for residential, retail, institutional, recreational, greenspace, and other categories from the

148 land-use layer were used to create a common diversity index (Shannon, 1948; Mavoa et al., 2018).  
149 The mean and maximum slope was derived from the elevation layer, as topography invariably  
150 affects travel modes. As a measure of accessibility, street intersections (3-way or above) were  
151 applied to this research. Park space and greenspace were also used in this research due to their  
152 impact on walking modes. As an additional measure of walking potential, we created a common  
153 walkability index built off of the work from Frank (2010). The reader can find the equation in the  
154 methods section of the supplementary materials.

155 We incorporated several measures from space syntax in this research. We utilized segment-  
156 based and angular segment analysis using Depthmap (version X)  
157 (<https://github.com/SpaceGroupUCL/depthmapX/>) and Java. Segment angular integration  
158 measures the number of direction changes needed to move from each street segment to all others  
159 within a set radius using the least angle measure of distance, while connectivity calculates the  
160 number of segments directly connected to each specific street segment (Hillier and Iida, 2005).  
161 Segment Angular Choice represents the number of shortest paths overlapping between all nodes  
162 in the graph (Varoudis et al., 2013). Metric reach computes the total length of streets accessible  
163 from the mid-point of each segment within a parametrically defined metric distance, while  
164 directional reach calculates the total street length accessible from the mid-point of each segment  
165 within a specified direction change (Peponis J., 2008). We included connectivity, integration,  
166 choice, and metric and directional reach in this research.

### 167 *Formalizing the home-school environment*

168  
169 We used the reported **children's** home addresses and created a 1,600-meter Euclidean  
170 distance buffer in ArcGIS (ESRI, Version 10.8). This distance was selected because it is a  
171 reasonable walking distance for children (Sun et al., 2018) and has been touted as an area where

172 the majority of a child's physical activity occurs (Smith et al., 2017). All the aforementioned  
173 compositional and contextual neighbourhood factors were aggregated to this neighbourhood using  
174 an interpolation and a spatial joining technique for raster and vector based GIS layers, and results  
175 were then normalized by population or area (km) to minimize issues associated with the modifiable  
176 areal unit problem (Kwan and Weber, 2008).

177 *Measuring the dependent variable: a route detour index*

178  
179 In accordance with previous research (Buliung et al., 2013), we utilized a route detour  
180 index (RDI) to assess the magnitude of walking route deviation from the GIS shortest-route to  
181 school. A participatory GIS mapping exercise was first conducted with children to collect actual  
182 walking routes (AR). Each route was then digitized using GIS. The route accuracies were  
183 checked manually and corrected by researchers using GIS. The GIS derived shortest path routes  
184 (SP) between each child's residence and school were then calculated using ArcGIS's Network  
185 Analyst tool. See figure S2 in the supplementary materials for a typical route comparison. The  
186 AR and SP route lengths were then used to calculate the RDI, which was considered excess  
187 walking (i.e., percent route deviation) in this research. The equation can be found in the methods  
188 section in supplementary materials.

189 *Statistical and spatial autocorrelation measures*

190 To meet our first research objective (i), we applied statistical measures of central tendency  
191 on all candidate variables. Exploratory spatial data analysis (ESDA) was then utilized to examine  
192 the degree of spatial clustering. The global autocorrelation index, Moran's  $I$  (Moran, 1950) was  
193 first implemented. The outputs range from -1 to +1, where increased positive values demonstrate  
194 that observations close to one another are similar, and elevated negative values indicate spatial  
195 dispersion. A significant ( $p \leq 0.05$ )  $z$ -score was used to assess the index's significance. A local  
196 index of spatial association (LISA) was also implemented in this research to geovisualize the

197 spatial dependency of RDI values for each group. The Getis-Ord  $G_i^*$  index was selected and the  
198 results were used to create significant kernel density “hot-spot” and “cold-spot” maps (Getis and  
199 Ord, 1992).

200 *Preliminary data processing*

201 A standard protocol to screen significant independent variables and build a set of regression  
202 models to predict RDI and reach our second research objective (ii) was instituted. We assessed the  
203 histogram, skewness, and kurtosis values for each variable using SPSS software. From this  
204 preliminary analysis, our final sample size was  $n= 373$ . Additional screening protocols are  
205 exhibited in the methods section of the supplementary materials. Table 1 exhibits the final set of  
206 variables used in this research, descriptive statistics, and Moran’s  $I$   $z$ -score results.

207

208

**Table 1**Descriptive statistics and spatial autocorrelation results for all final model variables ( $n = 373$ )

Variable	Description	Scale	Mean $\pm$ SD	Share (%)	Source	Moran's $I^1$ (z-score)
<b>Dependent variable</b>						
Route detour index (RDI) <sup>§</sup>	Walking excess (i.e., % deviation from SP)	Cont.	2.01 $\pm$ 2.24	SV	SV	2.64***
<b>Independent variables</b>						
<i>Children characteristics</i>						
Male (ref: female)	Dummy; 1=yes, 0=no	Binary		.74	QUE	0.21
Age	Reported age of child	Cont.	13.31 $\pm$ .97		QUE	2.93***
Obese	Dummy, 1: yes, 0: no	Binary		.12	QUE	-1.13
Route distance 403m-804m	Dummy, 1=yes, 0=no (ref: 0m-402m)	Binary		.43	QUE	2.14**
Route distance 805m-1,600m	Dummy, 1: yes, 0: no	Binary		.40	QUE	3.20***
Route distance > 1,600m	Dummy, 1: yes, 0: no	Binary		.01	QUE	0.27
Easy road crossings	Dummy, 1: yes, 0: no	Binary		.79	QUE	-0.19
Safe walking	Dummy, 1: yes, 0: no	Binary		.69	QUE	0.22
Walk to/from school	Percentage walking to and from school	Cont.	77.31 $\pm$ 14.40		QUE	8.40***

Notes: <sup>§</sup> = transformed by square root, <sup>‡</sup> = transformed to z-scores. \* < 10% chance random pattern; \*\* < 5% chance random pattern; \*\*\* < 1% chance random pattern. <sup>1</sup> = conceptualization of spatial relationship was inverted distance weighting.

Acronym codes: QUE = Questionnaire; GOV = government data sources; SV = computed study variable, Cont. = continuous variable

210 A hierarchical modelling protocol was implemented in this research due to the inherent  
211 structuring of factors influencing children's AST (Noland et al., 2014). A total of eight global (i.e.,  
212 ordinary least squares) and spatial models were developed, stratified by children's accompaniment  
213 level (i.e., unaccompanied versus accompanied):

214 *Model 1&5: child characteristics only*

215 *Model 2&6: child + parent/household*

216 *Model 3&7: child + parent/household + urban design*

217 *Model 4&8: child + parent/household + urban design + neighbourhood*

218

219 Four ordinary least-squares regression (OLS) models (i.e., models 1-4) were developed to  
220 highlight important global RDI correlates. The significant independent variables were manually  
221 entered into SPSS software at each stage. The Akaike Information Criterion (AIC) and coefficient  
222 of determination ( $R^2$ ) were used to assess each model's robustness. The standardized residuals were  
223 tested using global Moran's  $I$  to assess possible model misspecification. Considering the degree  
224 of spatial dependency (38%) among the independent variables (see Table 1), and to reduce OLS  
225 model violations, spatial regression models were tested.

226 Two spatial autoregression models were tried in this study to account for spatiality among  
227 the research variables. A spatial lag model and spatial error model (SEM) were developed using  
228 Geoda software version 1.2 (<http://geodacenter.github.io/index.html>); the latter proved the most  
229 robust and selected for this research. The SEM is an extension of the OLS model and belongs to a  
230 family of spatial autoregressive models where the residuals are assumed spatially dependent  
231 (Golgher and Voss, 2016). The hierarchical SEM models (models 5-8) for each children's group  
232 (i.e., unaccompanied and accompanied) were created using the independent variables utilized in  
233 the OLS models. Additional detail regarding the SEM model can be found in the supplementary  
234 materials methods section.

## 235 **Results**

236 *Descriptive Statistics*

237

238           The first objective (i) in this study was to empirically and spatially describe our sample in  
239 a Turkish context. The gender split was nearly equal (48.6% and 51.2% for males and females  
240 respectively). The average age was 13.1 (SD =.929) and 44.5% of the students were from the 6<sup>th</sup>  
241 grade; 30.1% of the students were from the 7<sup>th</sup> grade, and 25.4% of the students were from the 8<sup>th</sup>  
242 grade. Most children walked to school (71.8%) and 28.5% of these walked alone. There were  
243 marginal differences between the proportions of children who walked to and from school (69.7%),  
244 versus those who walked one-way (78.0%). In terms of parent characteristics, we observed that  
245 nearly half of the parents in the sample had at least attended a secondary school (i.e., college). The  
246 average household income was 2,279.37 Turkish Liras (TRY) and the mean number of  
247 automobiles per household was 1.55 (SD = .600). Table S2 displays the full summary statistics of  
248 the children and parent participants.

249           We observed that unaccompanied children travelled shorter distances to school and  
250 deviated less from the SP than their accompanied counterparts. The mean distance between the  
251 AR (95% CI: 612.95-722.44) and the SP (95% CI: 563.54-656.27) was 57.99 meters, representing  
252 an 8.68% increase over the SP route distance for this group. Among accompanied children, the  
253 mean difference between the AR (95% CI: 706.18-808.12) and SP (95% CI: 643.70-733.94) was  
254 68.33 meters; representing a 9.02% difference. The statistical trends of each children group's route  
255 behaviors are shown in supplementary table S3.

256 *Spatial analysis and geovisualizations*

257           The geovisualization of statistically significant ( $p < 0.05$ ) Getis-Ord  $G_i^*$  z-scores (i.e.,  
258 “hotspot/cold-spot” mapping) of excess travel (i.e., RDI) among our two children groups are

259 shown in figure S3 in the supplementary materials. We discovered that increased values (i.e.,  
260 “hot-spots”) for both groups were largely located in the central section/coastal area of the study  
261 area, while reduced values (i.e., “cold-spots”) occurred in the northeast areas (Figure S3a). For  
262 unaccompanied children, we discovered dispersed significant “hot-spots” in the northern and  
263 southeastern sections; and “cold-spots” were found in western/coastal areas (Figure S3b).  
264 Contrastingly, for accompanied children, we found significant “hot-spots” in the northwest  
265 section of the study area and a solitary “cold-spot” in the northwest coastal area (figure S3c).  
266 These outcomes validate that excess walking behaviors are spatially variant.

#### 267 *Modelling results: Unaccompanied children*

268  
269 The diagnostic and coefficient results from the hierarchical OLS and SEM regression  
270 models for unaccompanied children walkers are displayed in Table 2, thereby reaching our  
271 second research objective (ii). The baseline OLS models (1-4) displayed low to moderate  
272 performance, with the full model (4) being the strongest ( $R^2 = .426$ ,  $AIC = 797.15$ ).  
273 Multicollinearity was not found among our models (max VIF = 8.43). Due to the accounting of  
274 spatial effects, each SEM model outperformed the OLS models, with the full model (model 8)  
275 showing improvements of 1.38% and 0.11% for  $R^2$  and AIC indices, respectively, over the full  
276 OLS model. Provided the strength of the SEM outputs, we focus on these coefficients.

277 Across each of the SEM models (4-8), several children attributes and perceptual factors  
278 were found to be statistically significant ( $p < 0.05$ ). We found that age consistently impacted  
279 excess travel among unaccompanied children negatively (max  $\beta = -.384$ ) while distance had  
280 significant positive associations (805-1600 meters,  $\beta = 2.42$ ; > 1600 meters,  $\beta = 6.85$ ). Perceived  
281 road crossing ease consistently had an inverse effect (max  $\beta = -.895$ ) on RDI. In terms of  
282 parental effects, we observed that perceived greenspace diversity (max  $\beta = .533$ ) and household

283 automobiles ( $\max \beta = .547$ ) had a positive impact on excess walking for this group. Although  
284 urban design measures were not strongly associated with RDI, we noted that land-use diversity  
285 had a positive influence ( $\max \beta = 5.92$ ).

286 *Modelling results: Accompanied children*

287

288           The significant relationships between RDI and the independent variables influencing  
289 excess travel among accompanied children are presented in Table 3. The strength of the OLS  
290 models ranged from low to moderate: the full model (4) was the strongest, exhibiting an  $R^2 =$   
291  $.333$  and  $AIC = 785.22$ . Multicollinearity amongst the independent variables did not exceed the  
292 threshold ( $\max VIF = 9.60$ ). Each SEM model (4-8) was marginally stronger than the OLS  
293 models, which is due to controlling for spatial effects. We found that the full SEM model (model  
294 8) exhibited a slight improvement of 1.18% and 0.07% over the full OLS model in terms of  $R^2$   
295 and AIC, respectively. Given that the full SEM (8) was the most robust ( $R^2 = .337$ ,  $AIC =$   
296  $784.65$ ), we will focus on these coefficients.

297           Longer distances to school had a positive and significant ( $p < 0.05$ ) effect on RDI in each  
298 model: distances between 805-1600 meters ( $\beta = 2.74$ ) had the strongest impact. A child's gender  
299 (i.e., male) ( $\beta = -.986$ ) exerted a negative effect on excess travel. Of the parental and household  
300 characteristics, reduced income ( $\max \beta = .977$ ) had the most influence on RDI. Parental attitudes  
301 had no impact on RDI. Connectivity, measured from space syntax, exerted a significantly ( $p <$   
302  $0.05$ ) negative effect ( $\beta = -4.60$ ) on the dependent variable. Other significant ( $p < 0.05$ )  
303 neighbourhood factors positively affecting RDI included maximum slope ( $\beta = .126$ ) and land-  
304 use mix ( $\beta = 6.86$ ).

## 394 **Discussion and conclusions**

395 Limited research exists on the factors impacting children's excess walking to school,  
396 especially in understudied regions of the world, such as Turkey (Ozbil et al., 2021), leaving us  
397 with scant insights on how to elevate children's AST. Unlike previous research, we stratified our  
398 analysis between unaccompanied and accompanied children to better understand the important  
399 factors on excess walking to school. Using a robust empirical and spatial modelling approach to  
400 control for the geographical differences among children/parent characteristics and perceptions,  
401 neighborhood context and composition, our results have provided new understandings on  
402 important predictors of excess walking to school for two distinct groups of children. The  
403 following sub-sections discuss the key findings from this study.

### 404 *Descriptive and spatial analysis of walking behaviors*

405 Our first research objective (i) was to gain a better understanding of children's walking  
406 behavior to school empirically and spatially in Turkey. We found that unaccompanied children  
407 travelled shorter distances to school and detoured less from the shortest route (i.e., low RDI).  
408 Their actual routes to school, and associated RDI values, were 11.78% and 13.42% less than  
409 accompanied children, respectively. The ESDA and geovisualizations indicated that excess  
410 walking (i.e., RDI) to school not only differed based on accompanied status but depended on the  
411 neighborhood locations. The outcome supports previous research that AST is not a generalized  
412 phenomenon (Mitra et al., 2010), and emphasizes the importance of placed-based interventions  
413 to encourage additional –exploratory– walking to school.

### 414 *Childhood character and attitude*

415           The second (ii) objective in this research was to understand how children’s character and  
416 perceptions impacted their route choices whether unaccompanied or accompanied. Consistent  
417 with previous works, the home-school distance was an important correlate among both groups  
418 (Easton and Ferrari, 2015). We found that older unaccompanied children engaged in less excess  
419 walking to school than their accompanied classmates. Our finding is correlated with Davison et  
420 al., (2008). Interestingly, weight status (i.e., obese) had a positive association with excess  
421 walking among unaccompanied children. One feasible explanation is that independent children  
422 may be inclined to visit unhealthy food outlets during the school journey **which corresponds to**  
423 **work from Madsen et al., (2009). This evidence should prompt the coordination of nutrition**  
424 **programming with safe routes to school (SRTS) plans when designing walkable environments**  
425 **for children (Fraser et al., 2012).** Our results showed that accompanied girls engaged in more  
426 excess walking to school (i.e., higher RDI) than boys in this study. While contrasting with some  
427 past research (Buliung et al., 2017), we **contend** that safety is elevated when this group is  
428 accompanied and induces route choices which deviate from the shortest path to school.  
429 Children’s perceived road crossing ease hindered excess walking among both children groups –  
430 the strongest association was among unaccompanied children. We can infer that easy road  
431 crossings present opportunities for children to choose the shortest path because it is the most  
432 efficient and likely perceived as safe. Additional research is needed to better understand the local  
433 neighborhood conditions where this relationship holds.

#### 434 *Parent and household factors*

435           Among the parental and household factors impacting children’s excess travel, we  
436 consistently found household SES influenced children’s excess walking to school. We noted that  
437 household automobile access was positively linked to excess walking among unaccompanied

438 children. While this contradicts some past research (Carver et al., 2013), our finding is promising  
439 in that despite the option to be driven to school, this group prefers to take longer routes to school,  
440 potentially reducing negative impacts on the environment (Yang et al., 2016). We also  
441 discovered that accompanied children in low-income households (i.e., income  $\leq$  1400TRY)  
442 engaged in excess walking to school. Our finding lends credence to past literature (Ross and  
443 Kurka, 2021) and highlights that such households may reside in neighborhoods with incomplete  
444 sidewalks, unsafe streets, and/or don't have access to an automobile, which could require  
445 children to **detour more often** (i.e., excess walking) **to find "easier" walking paths** to school. **As**  
446 **suggested by Müller et al., (2020), walking school busses, where parental groups escort children**  
447 **to their respective schools, could be one intervention to encourage walking safely.** Surprisingly,  
448 we did not find any relationship between perceived traffic safety and excess walking. A notable  
449 link was observed regarding greenspace diversity and unaccompanied children's excess travel.  
450 **The outcome should be considered by planners and policy-makers examining urban**  
451 **environments lacking greenspace. Past works indicate that this can allay parental fears regarding**  
452 **children's AST (Evers et al., 2014), and promote vital prosocial behaviours among adolescents**  
453 **(Putra et al., 2020).**

#### 454 *Urban design, neighbourhood, and excess walking to school*

455 Our lone finding on the effect of urban design on children's excess travel to school  
456 occurred largely among accompanied children. We demonstrated that space syntax derived  
457 connectivity negated excess walking to school, especially for accompanied children. Supported  
458 in part by Kaplan (2016), our results show that syntactically connected streets may be  
459 unattractive due to higher traffic densities and unsafe conditions; promoting children to find  
460 alternative walking routes to school. Surprisingly, no relationship was found between

461 neighbourhood walkability and excess travel among either group. A comparable surrogate, land-  
462 use diversity, universally promoted excess travel for both groups. Aligned with prior research,  
463 our finding also suggests that this metric has a positive impact on walking regardless of a child's  
464 accompaniment status (Moran et al., 2016). **The weak associations between excess walking,**  
465 **urban design and home-neighborhood walkability relative to the importance of social**  
466 **characteristics (i.e., household factors ) are not surprising in light of prior works (Mitra and**  
467 **Buliung, 2014; Wong et al., 2011). Our findings suggest that planners and policy-makers should**  
468 **concentrate on assessing social neighborhood conditions such as cohesion and connection when**  
469 **designing impactful interventions (Hino et al., 2021).**

#### 470 *Limitations and conclusion*

471 Despite our research contributions, the limitations of this study should be noted. The data  
472 collected in this study was cross-sectional and causal relationships could not be verified. We also  
473 did not request that children indicate who they travelled with when walking to school: the survey  
474 simply questioned if children were accompanied or not. This provides a critical venue for future  
475 research, as past works have shown that children's AST differs when walking with an adult  
476 versus a peer (Ahern et al., 2017). **As recent research indicates (Buliung et al., 2021), how**  
477 **"excess travel" is conceived of can differ among researchers, parents, and children. These are**  
478 **shaped by a person's intra/inter-personal concerns, including work-school constraints, and**  
479 **required family chores/activities, as well as specific street network qualities which impact excess**  
480 **walking conceptually and practically. Future research should acknowledge these differing**  
481 **perspectives when examining children's AST.** Our incorporation of a Euclidean 1,600-meter  
482 buffer encircling each child's residence may be a limitation. A more refined scale focused on the  
483 detailed walking route conditions using GPS, similar to work from Clark et al., (2016) will fuel

484 future work. We also acknowledge that our choice of using a VIF threshold value of ten is  
485 relatively high and this index has noted limitations (Alauddin and Nghiem, 2010). Therefore,  
486 multicollinearity may still be present in our models and coefficient interpretation (i.e., magnitude  
487 and directionality) should be viewed with caution. Overall, the discoveries provided in this study  
488 should be acknowledged and used by local stakeholders in similar regions of the world to assist  
489 with creating child-friendly environments which encourage children’s safe walking routes to  
490 school while alone or with someone.
